t_r Raise time

t_s Settling time

Canonical 2nd Order Lowpass System

$$G(s) = \frac{\omega_n^2}{s^2 + 2\zeta\omega_n s + \omega_n^2}$$

$$\sigma = \zeta\omega_n$$

Assignment Project Exam Help
 $\omega_d = \omega_n \sqrt{1 - \zeta^2}$

- Assume stability and underdamping ($0 < \zeta < 1$), i.e. the poles have nonzero imaginary parts and negative real parts.
- We will see that overshoot, rise time and settling time specs will impose constraints on the permitted pole locations

Partial Fraction

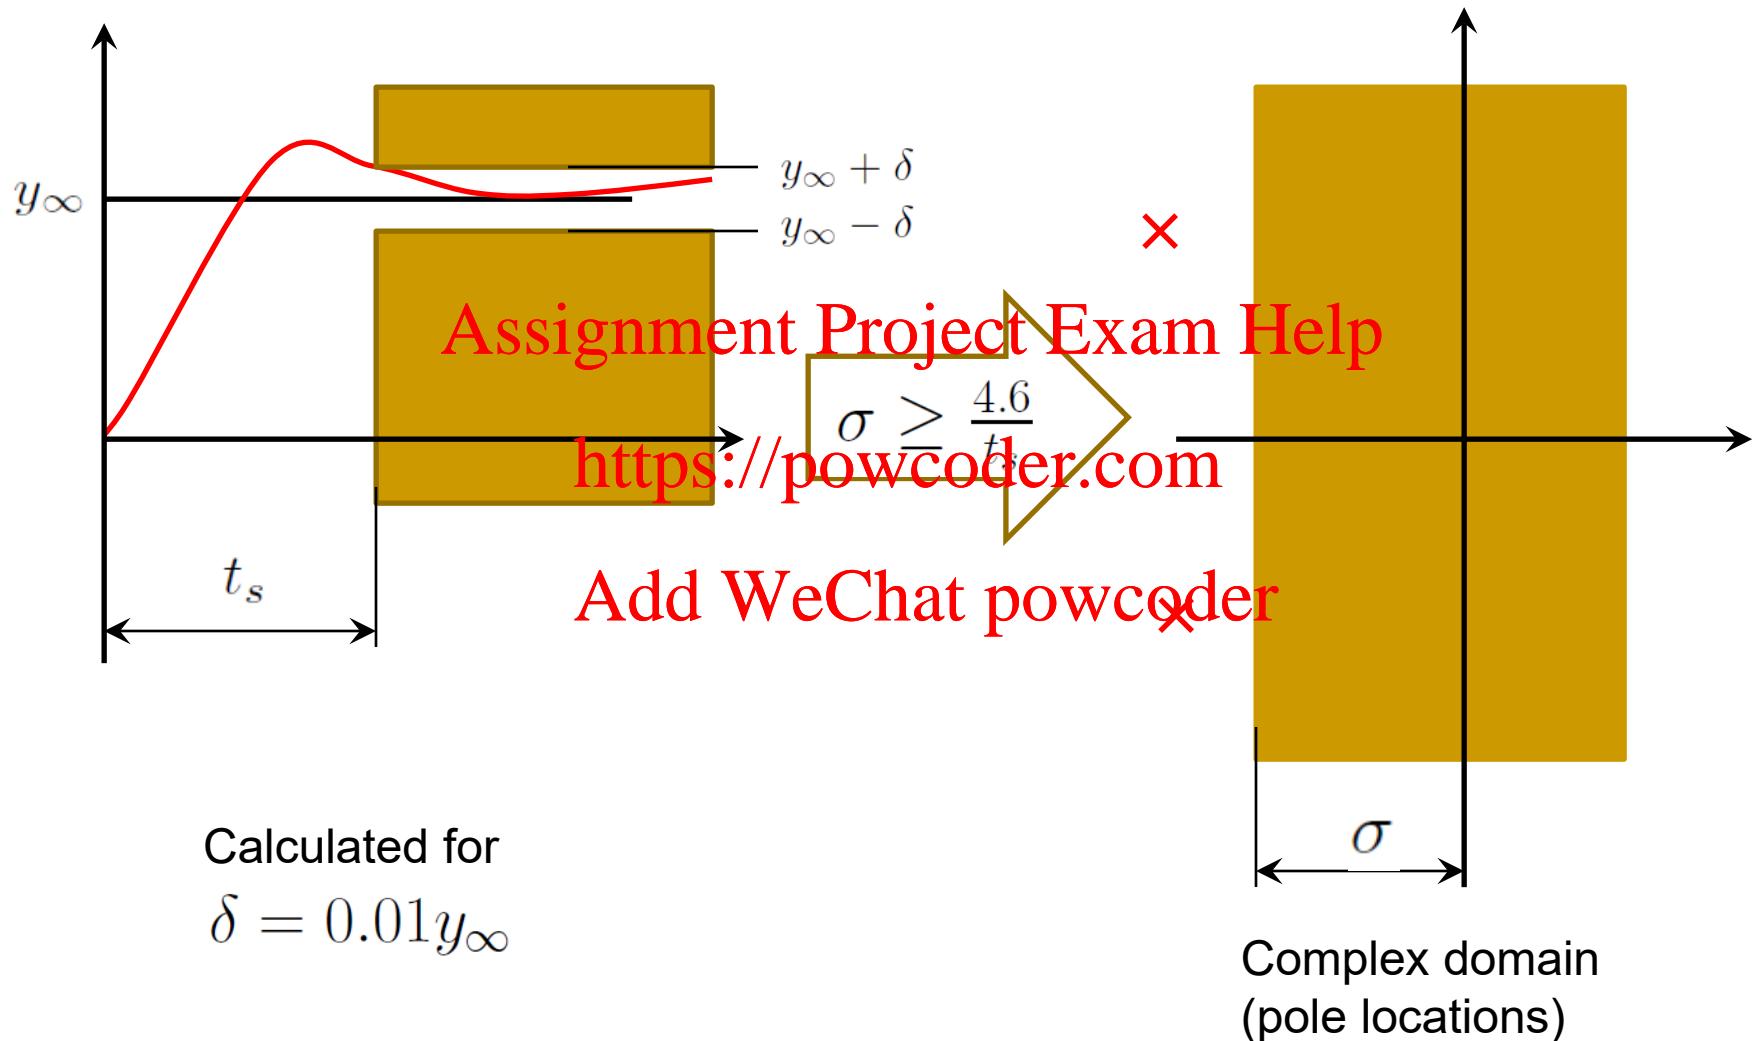

- Denote step response by $y(t)$

$$Y(s) = \frac{G(s)}{s} - \frac{\omega_n^2}{s(s^2 + 2\zeta\omega_n s + \omega_n^2)} - \frac{\omega_n^2}{s((s+\sigma)^2 + \omega_d^2)}$$
$$= \frac{1}{s} - \frac{\frac{1}{2\zeta\omega_n}}{(s^2 + 2\zeta\omega_n s + \omega_n^2)} - \frac{s}{(s^2 + 2\zeta\omega_n s + \omega_n^2)}$$

Table look-up:

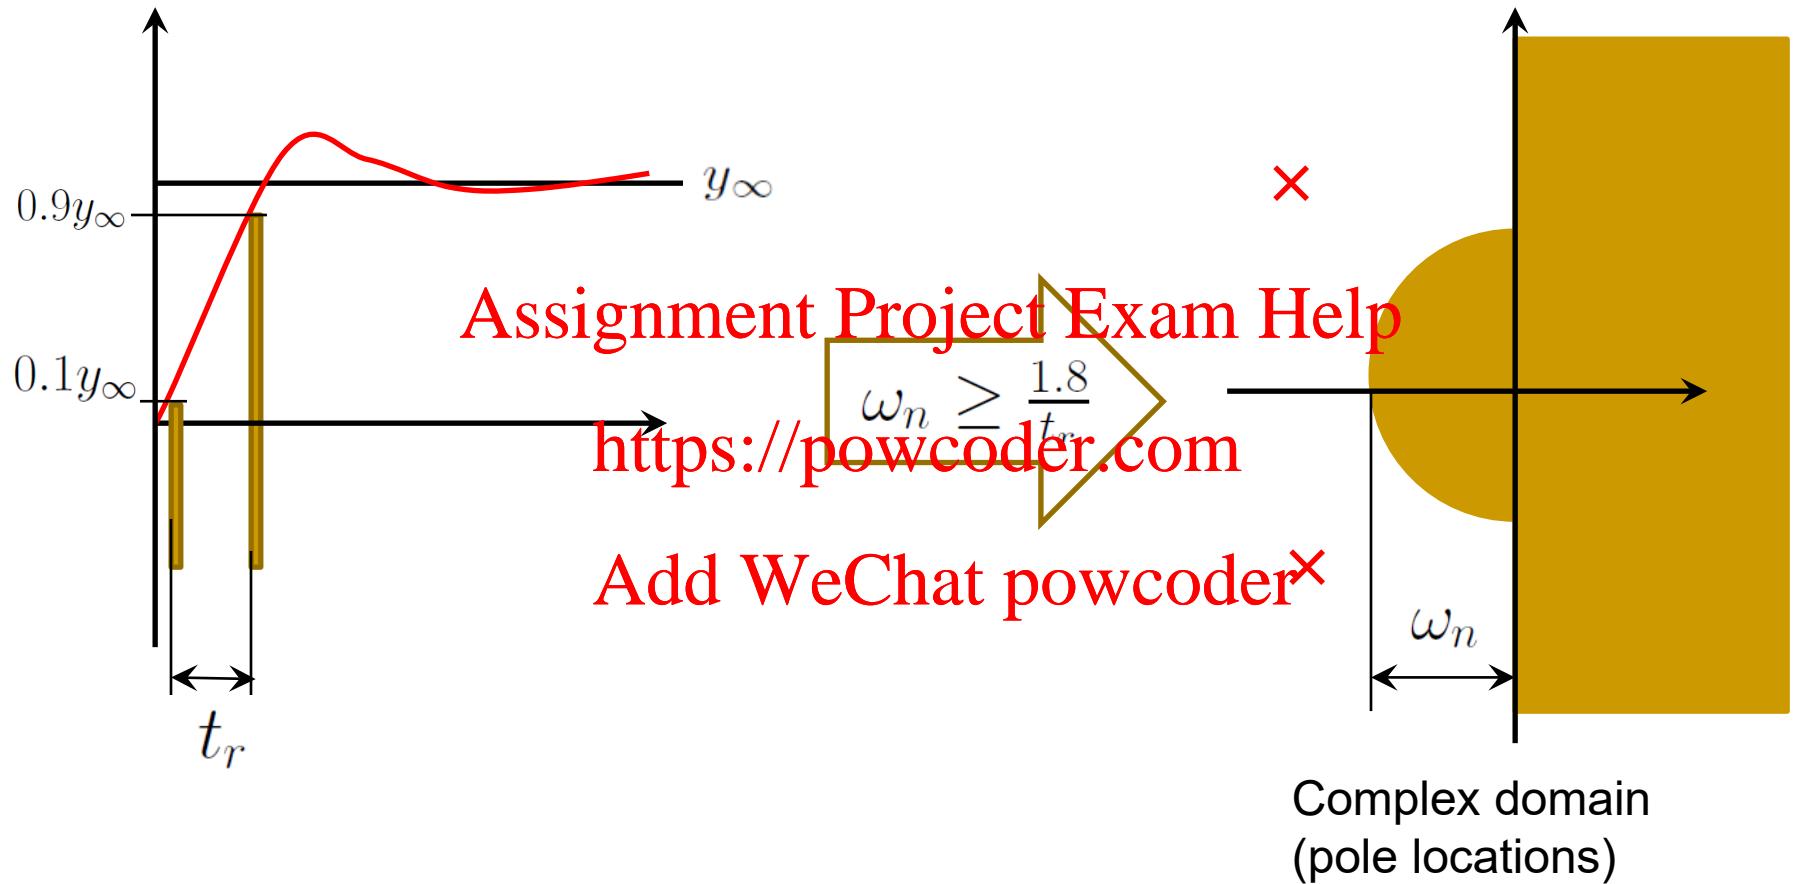

$$y(t) = 1 - \frac{\zeta}{\sqrt{1 - \zeta^2}} e^{-\sigma t} \sin(\omega_d t) - e^{-\sigma t} \cos(\omega_d t)$$

Settling time

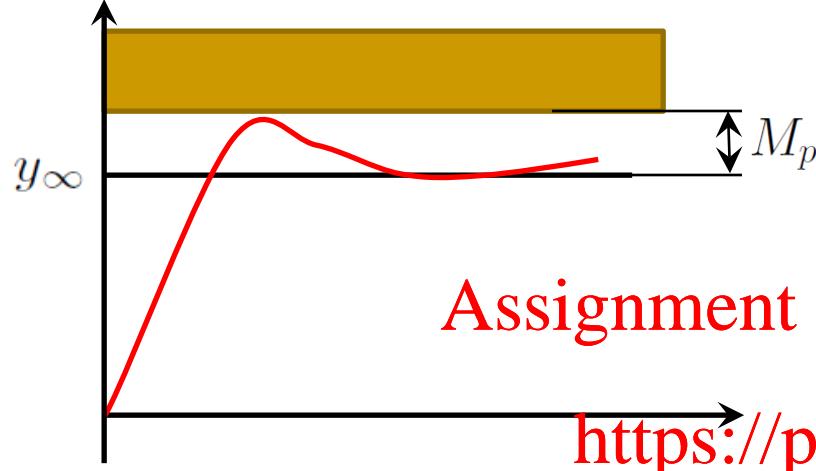

Brown colour represents a “forbidden region”.

Rise time

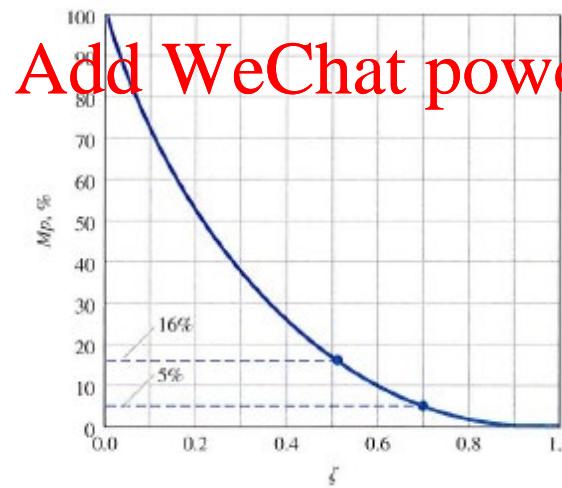

Brown colour represents a “forbidden region”.

Overshoot

Complex domain
(pole locations)

Summary

- Given a combined requirement on overshoot, rise time and settling time, we could get:

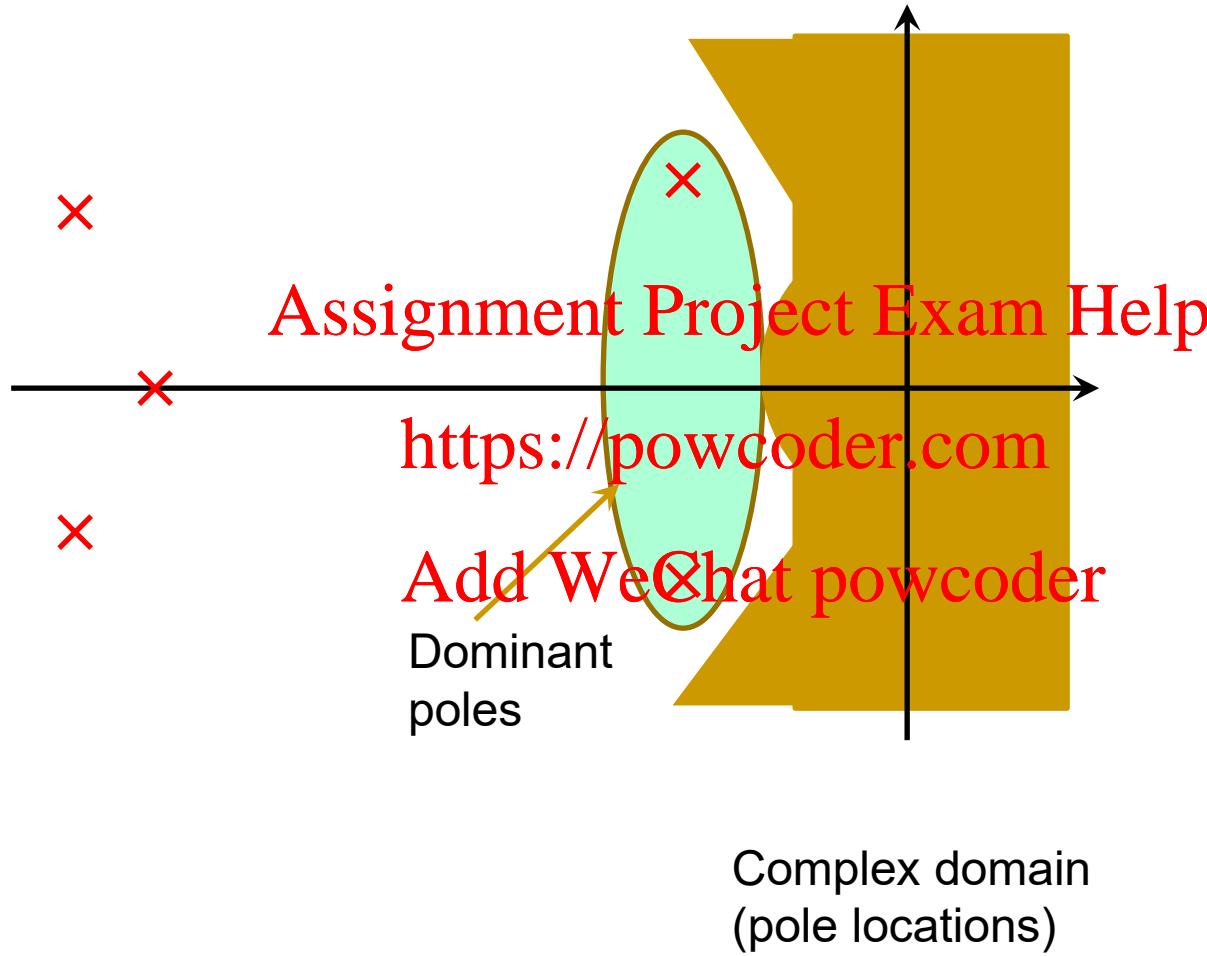

Brown colour represents a “forbidden region”.

From 2nd to Higher Order

- Formulas for canonical 2nd order systems provide a “rule of thumb” for designing higher order lowpass systems [Assignment Project Exam Help](#)
- They work well if there are two complex conjugate, stable, “dominant” poles that satisfy the required constraints. (Dominant means all other poles are far to the left, i.e. their modes decay much more rapidly)
<https://powcoder.com>
[Add WeChat powcoder](#)
- The formulas also work for proper stable systems with zeros all much larger than the dominant poles.

Graphical illustration

Approximating by 1st Order System

- By designing a single, real-valued dominant pole, we could even use a 1st order approximation. Even simpler!
- However, ~~Assignment Project Exam Help~~ of design freedom.
- E.g. in a 1st order step response, the rise time is always about the same as the settling time.
~~Add WeChat powcoder~~
- But for a 2nd order system, we could potentially place the poles so that the rise time is much shorter → a controller that's more responsive, at the expense of overshoot.
- Higher order systems also have superior noise rejection properties (more after we introduce freq. response)

Fundamental trade-offs

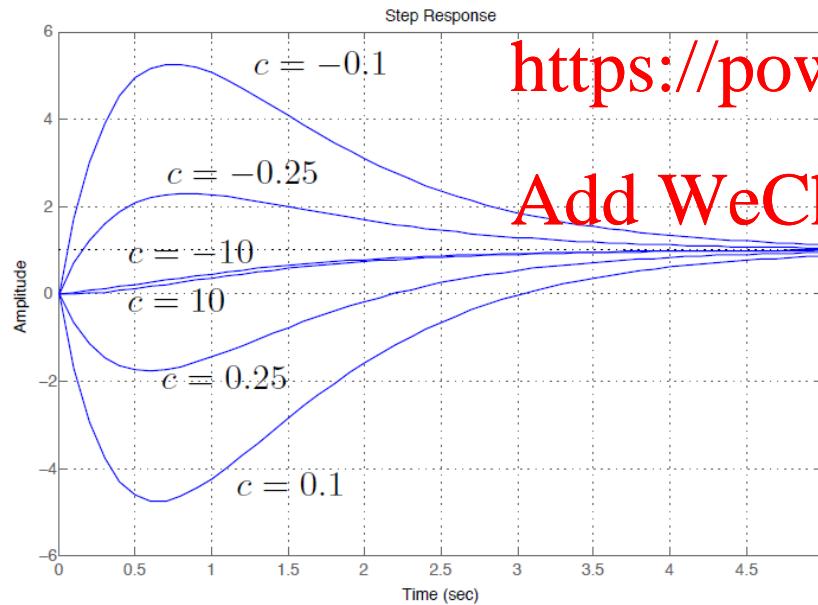

- Sometimes, a step-response specification may not be achievable, due to a clash with another ~~Assignment Project Exam Help spec.~~
- In other words, ~~https://powcoder.com~~ there may be fundamental limitations, or ~~trade-offs~~ in performance.
Add WeChat powCoder
- We look next at a couple of the trade-offs caused by zeros

Example (real unstable zero)

- Consider this system with zero at $s = c$

$$G(s) = \frac{-(s - c)}{(s + 1)(s + 5)}$$

Assignment Project Exam Help

<https://powcoder.com>

Add WeChat powcoder

Overshoot: when zero is negative and small relative to the dominant pole at -1.

Undershoot: when zero is positive.

Slow zeros seem to have biggest impact.

Fundamental limitation:

(undershoot vs. settling time with unstable, real zero)

Suppose $G(s)$ is a stable transfer function, with $G(0) = 1$ and $G(c) = 0$ for a real valued $c > 0$, such that the step response $y(t)$ satisfies

$$1 - \delta \leq |y(t)| \leq 1 + \delta \quad \text{for all } t \geq t_s \quad (\delta \text{ small } \sim 0.01)$$

'settling time' - see slide 19

Then the step response exhibits undershoot at the level of

Add WeChat powcoder

$$M_u \geq \frac{1 - \delta}{e^{ct_s} - 1} \approx \frac{1}{ct_s} \quad \text{for small } ct_s \text{ and } \delta$$

Proof:

Define $v(t) = 1 - y(t)$ so that $\max_{t \geq 0} v(t) = 1 + M_u > 0$ and $|v(t)| \leq \delta$ for $t \geq t_s$.

Assignment Project Exam Help

We have $V(s) = (1 - G(s))\frac{1}{s}$ and $V(c) = \frac{1}{c} = \int_0^{\infty} v(t)e^{-ct} dt$.

okay because
 $c \in \text{ROC}(V)$
 $= \{s : \Re(s) > 0\}$

As such,

$$\begin{aligned}\frac{1}{c} &= V(c) = \int_0^{t_s} v(t)e^{-ct} dt + \int_{t_s}^{\infty} v(t)e^{-ct} dt \\ &\leq (1 + M_u) \int_0^{t_s} e^{-ct} dt + \delta \int_{t_s}^{\infty} e^{-ct} dt \\ &= (1 + M_u) \frac{1 - e^{-ct_s}}{c} + \delta \frac{e^{-ct_s}}{c}.\end{aligned}$$

Add WeChat powcoder

<https://powcoder.com>

Fundamental limitation:

(overshoot vs. settling time with slow, stable real zero)

Suppose $G(s)$ is a stable transfer function, with $G(0) = 1$, $G(c) = 0$ for a real valued $c < 0$ and a dominant pole having real part $-p < 0$, such that

(i) $\eta \doteq \left| \frac{c}{p} \right| \ll 1$ and (ii) the unit step response $y(t)$ satisfies

$$|1 - y(t)| \leq K e^{-pt} \text{ for } t \geq t_s \text{ and some } K > 0,$$

where t_s is the settling time for a suitable δ .

Then the step response has a percentage **overshoot**

$$M_p \geq \frac{1}{e^{-c t_s} - 1} \left(1 - \frac{K\eta}{1 - \eta} \right).$$
